

Case for **abscess** after surgery

A 36-year-old woman with history of two cesarean section and concomitant oophorectomy due to multiple ovarian tumor was admitting to a teaching hospital with abdominal pain from last week. Ultrasonography showed multiple ovarian cystic mass suspicious for dermoid in the right ovary. On laparoscopy, left ovary was absent and uterus was normal, while right ovary presented ten dermoid cysts with adhesion to sigmoid and small bowel. All cysts were enucleated and removed laparoscopically. The patient had an uncomplicated recovery and was discharged two days after surgery. pathology confirmed the diagnosis of multiple mature cystic teratoma.

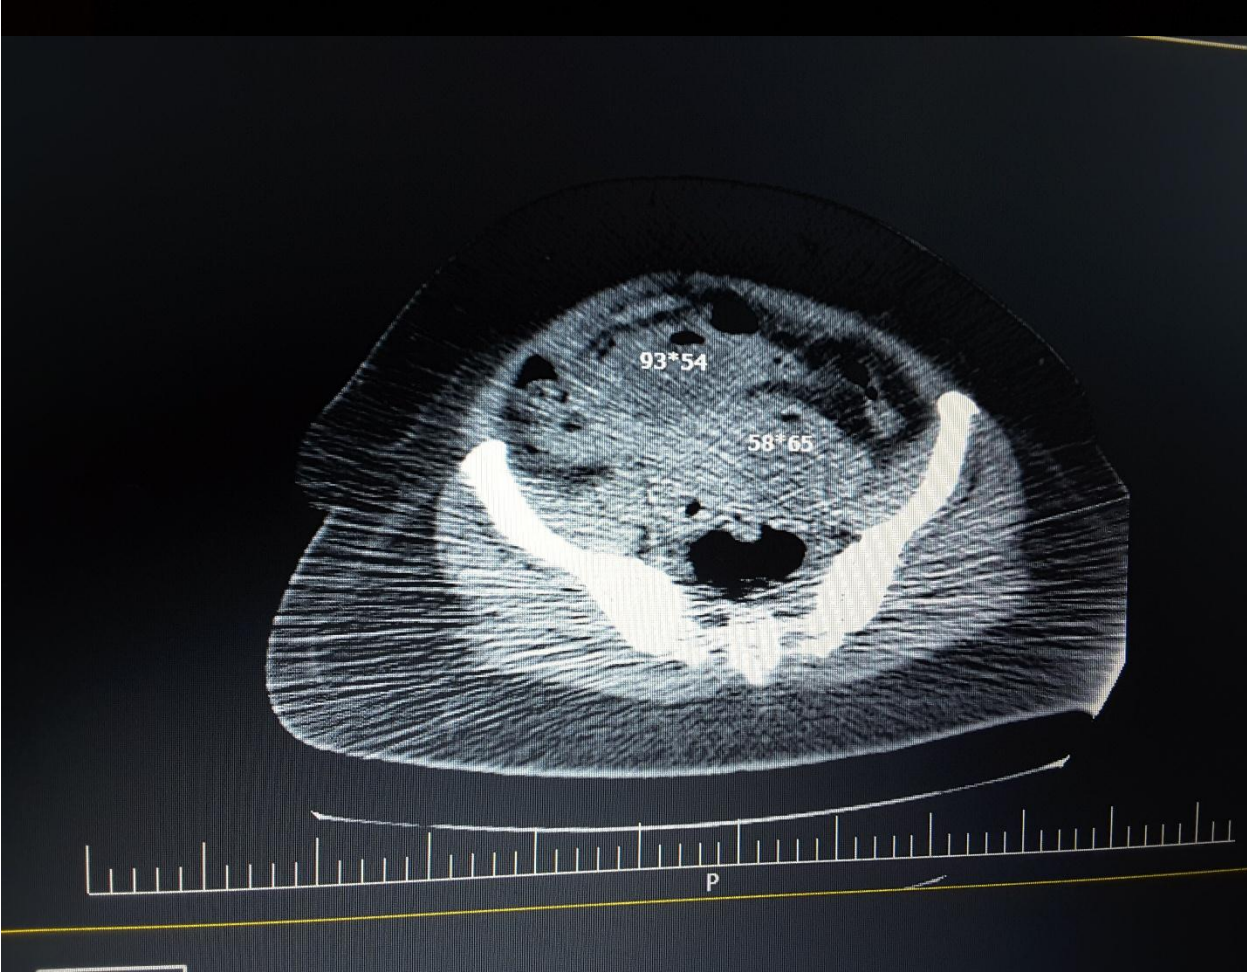

After the surgery, we referred her for Abdominal and Pelvic + CM Spiral MDCT; report of CT was:

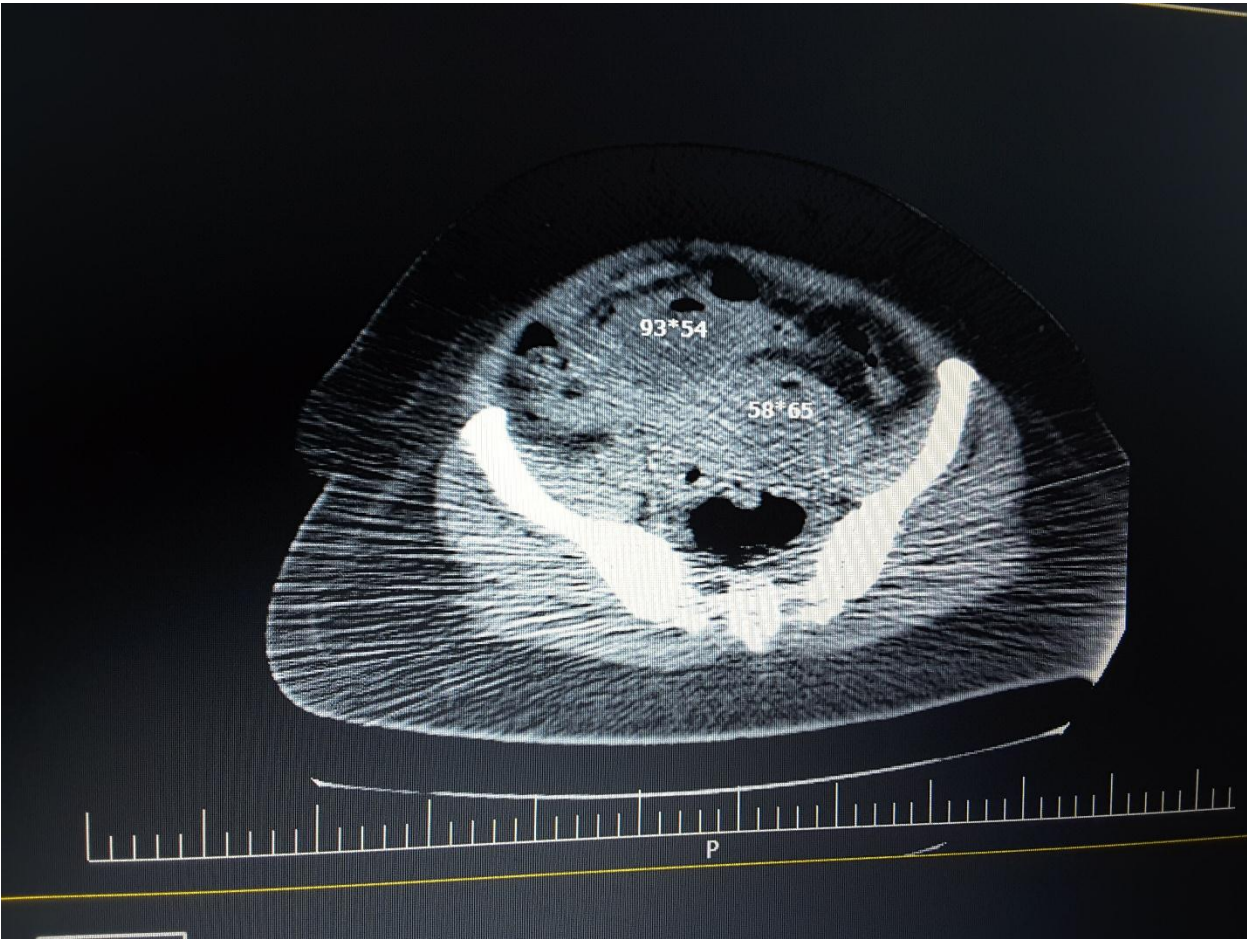

***There are thick wall collection about 93×54 mm anteriorly to uterus and right side of pelvic cavity and collection about 58×65 mm in left side of uterus.***

Mild free fluid is seen in pelvic cavity.

We show the section of CT that clearly presented both collections
